Abstract*—Milenage algorithm applies the block cipher Rijnadael (AES) with 128 bit key and 128 bit block size. This algorithm is used in the 3GPP authentication and key generation functions (f1, f1*, f2, f3, f4, f5 and f5*) for mobile communication systems (GSM/UMTS/LTE). In this paper a modification of Milenage algorithm is proposed through a dynamic change of S-box in AES depending on secret key. To get a new secret key for every authentication process we add the random number (RAND) transmitted from the authentication center (AUC) to the contents of the fixed stored secret key (K_i) and thus the initialization of the AES will be different each new authentication process . For every change in secret key a new S-box is derived from the standard one by permuting its rows and columns with the help of a new designed PN sequence generator. A complete simulation of modified Milenage and PN sequence generator is done using Microcontroller (PIC18F452). Security analysis is applied using Avalanche test to compare between the original and modified Milenage. Tests proved that the modified algorithm is more secure than the original one due to the dynamic behavior of S-box with every change of the secret key and immunity against linear and differential cryptanalysis using Avalanche tests. This makes the modified Milenage more suitable for the applications of authentication techniques specially for mobile communication systems.

I. INTRODUCTION

Authentication includes the authenticity of the subscriber as well as the network. Authentication of mobile subscribers and network operators is a challenge of future researchers due to increasing security threats and attacks with the enhanced volume of wireless traffic. Authentication schemes in mobile communication systems are initiated during international mobile subscriber identity attach, location registration, location update with serving network change, call setup, activation of connectionless supplementary services and short message services (SMS).

Milenage algorithm is used for generating authentication and key agreement of cryptographic generating functions (MAC, XRES, CK and IK). The main core of Milenage algorithm is the Advanced Encryption Standard (AES) [1] which launched as a symmetrical cryptographic standard algorithm by the National Institute of Standard and Technology (NIST) in October 2000, after a four year effort to replace the aging DES. The Rijndael proposal for AES defined a cipher in which the key length can be independently specified to be 128 , 192 or 256 bits but the input and output block length is 128 bits [2],[3]. Four different stages are used in AES : Sub Byte transformation, Shift Rows, Mix Columns and Add Round Key. For both encryption and decryption, the cipher begins with an Add Round Key stage, followed by nine rounds that each includes all four stages, followed by a tenth round of three stages. [4].

This paper is organized as follows: In Section II, authentication schemes in mobile communications are described. In Section III, a proposed authentication scheme is presented depending on the dynamic change of S-box in AES, the new secret key for every authentication process and the new PN sequence generator. In Section IV, a complete simulation of the modified Milenage algorithm and the Avalanche test results are introduced. Discussions and Conclusions are presented in Section V.

II. AUTHENTICATION SCHEMES IN MOBILE COMMUNICATIONS.

(i) Global System for Mobile Communication (GSM) / General Packet Radio Service (GPRS) Authentication and Key Agreement vectors .

There exists a permanent, shared secret key K_i for each subscriber. This permanent key is stored in two locations: in the subscriber's SIM card and in the Authentication Centre (AuC). The key K_i is never moved from either of these two locations. Authentication of the subscriber is done by checking that the subscriber has access to K_i. This can be achieved by challenging the subscriber by sending a random 128-bit string random sequence number (RAND) to the terminal. The terminal has to respond by computing a one-way function with inputs of RAND and the key K_i, and returning the 32-bit output Signed Response (SRES) to the network. Inside the terminal, the computation of this one-way function, denoted by A3, happens in the Subscriber Identity Module (SIM) card. During the authentication procedure, a temporary session key Kc is generated as an output of another one-way function A8. The input parameters for A8 are the same as for A3: K_i and RAND. The session key Kc is subsequently used to encrypt communication on the radio interface. The serving network does not have direct access to the permanent key K_i, so it cannot perform the authentication alone. Instead, all relevant parameters, so called the authentication triplet (RAND, SRES and Kc) are sent to the serving network element Mobile Switching Centre/Visitor Location Register (MSC/VLR) or Serving GPRS Support Node (SGSN) in the case of General Packet Radio Service (GPRS) from the authentication center (AuC) [5], [6].

(ii) Universal Mobile Telecommunications System (UMTS)/ Long Term Evolution (LTE) /Advanced LTE Authentication and Key Agreement Vectors.

- Universal Mobile Telecommunications System (UMTS) Generation of Authentication vectors (Quintets) in the authentication center (AUC).

Upon the receipt of the authentication data request from the Visitor Location Register (VLR) / Serving GPRS Support Node (SGSN), The Home Location Register (HLR) / Authentication Centre (AuC) sends an authentication response back to the VLR/SGSN that contains an ordered array of n authentication vectors AV (1...n). The HLR/AuC starts with generating a fresh sequence number SQN and an unpredictable challenge RAND. The authentication vectors are ordered based on sequence number. [5].

There are eight Cryptographic functions used in UMTS/LTE/Advanced LTE Authentication and Key Agreement to generate Authentication vector (AV). f_0 is the random challenge-generating function. It should be a pseudo random number-generating function and map the internal state of the generator to the challenge value RAND, the length of RAND is 128 bits. The f_1 is the network authentication function, f_1* is the re-synchronization message authentication function, it is used to provide data origin authentication for synchronization failure information sent by the USIM to the AuC, f_2 is the user authentication function, f_3 is the cipher key derivation function , f_4 is the integrity key derivation function, f_5 is the anonymity key derivation function for normal operation and f_5* is the anonymity key derivation function for re-synchronization, f_5* is only used to provide user identity confidentiality during resynchronization. K is the subscriber authentication key stored in the USIM and at the AuC, The length of K is 128 bits. [5], [7], [8].

To generate authentication quintuple, the HLR\AUC computes a message authentication code for authentication MAC-A= f_1k(SQN || RAND || AMF), the length of MAC-A is 64bits. An expected response XRES = f_2k (RAND), the length of XRES is 64bits. a cipher key CK = f_3k (RAND), the length of CK is 128bits. An integrity key IK = f_4k (RAND) the length of IK is 128bits and an anonymity key AK = f_5k (RAND), the length of AK is 48bits that is used to conceal sequence number SQN, the length of SQN is 48bits, SQN= SQN $\oplus$ AK. The HLR/AuC aggregates the authentication token AUTN = SQN [$\oplus$ AK] || AMF (16bits) || MAC-A, the lengths of AUTN is 128bits that forms the quintet Q =AV= (RAND, XRES, CK, IK, AUTN). [7], [8], [9].

- Authentication and key derivation in the Universal Subscriber Identity Module (USIM).

Upon receipt of a (RAND, AUTN), the USIM computes the anonymity key AK = f_5k (RAND) and retrieves the unconcealed sequence number SQN = (SQN $\oplus$AK) $\oplus$ AK, XMAC-A = f_1k (SQN || RAND || AMF), the response RES = f_2k (RAND), the cipher key CK = f_3k (RAND) and the integrity key IK = f_4k (RAND) as shown in fig.2. [5], [6].

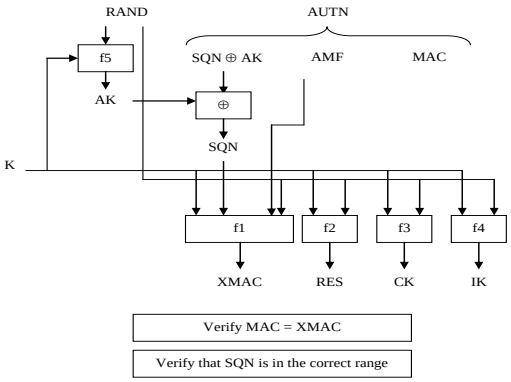

Figure 1. Authentication and key derivation in the Universal Subscriber Identity Module [7].

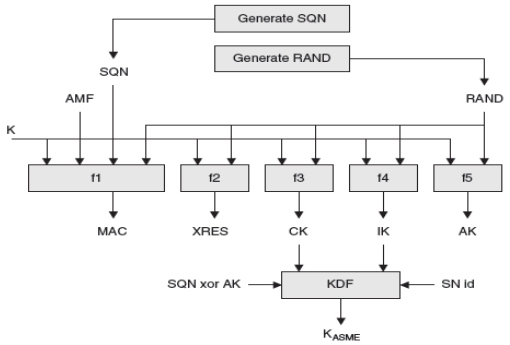
(iii) Long Term Evolution (LTE) /Advanced LTE Generation of Authentication Vectors in the Home Subscriber Server (HSS).

The LTE architecture is built on the existing architecture from UMTS. LTE standards reuse the authentication and key-agreement of UMTS. The LTE/Advanced LTE Authentication and Key Agreement (AKA) protocol also known as the Evolved Packet System (EPS) AKA protocol. The EPS-AKA protocol is executed between UE and the MME instead of between the USIM and the VLR/SGSN. The AuC generates UMTS AVs for EPS AKA in exactly the same format as for UMTS AKA. The Home Subscriber Server (HSS) part outside the AuC derives Local Master Key in EPS (KASME) from the CK and IK. EPS AV consists of [RAND, XRES, a local master key KASME and an AUTN] as shown in fig.1. [10], [11], [12].



AUTN = [SQN ⊕ AK || AMF || MAC].

UMTS (AV) = [RAND || XRES || CK || IK || AUTN].

EPS (AV) = [RAND || XRES || KASME|| AUTN].

Figure 2. Generation of UMTS and EPS authentication vectors. [6].

III. Proposed Authentication Scheme in Mobile Communication.

A modification of Milenage algorithm is proposed through a dynamic change of S-box in AES depending on the new secret key. To get a new secret key for every authentication process we add the random number (RAND) transmitted from the authentication center (AUC) to the contents of the fixed stored secret key (K_i) and so, the initialization of the AES will be different for each authentication process. For every change in secret key a new S-box is derived from the standard one by permuting its columns and rows with the help of a new designed PN sequence generator. Finally to get a strong Milenage algorithm generating all functions f1, f1*, f2, f3, f4, f5, and f5* and the outputs of the various functions used in User Authentication, Network Authentication, Data Integrity Check and Ciphering data. The outputs of the various functions are then defined as shown in fig.3.

- Output of f1 = MAC-A, where MAC-A[0] .. MAC-A[63] = OUT1[0] .. OUT1[63]
- Output of f1* = MAC-S, where MAC-S[0] .. MAC-S[63] = OUT1[64] .. OUT1[127]
- Output of f2 = RES, where RES[0] .. RES[63] = OUT2[64] .. OUT2[127]
- Output of f3 = CK, where CK[0] .. CK[127] = OUT3[0] .. OUT3[127]
- Output of f4= IK, where IK[0] .. IK[127] = OUT4[0] .. OUT4[127]
- Output of f5= AK, where AK[0] .. AK[47] = OUT2[0] .. OUT2[47]
- Output of f5* = AK, where AK[0] .. AK[47] = OUT5[0] .. OUT5[47]

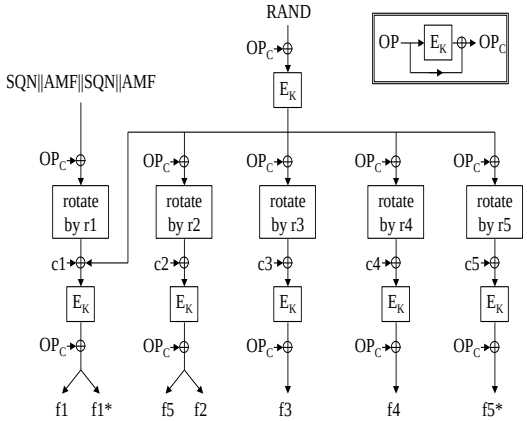


Figure 3. Computation of the MILENAGE functions. [13].

Upgrade of S-box (Dynamic S-box) depends on the new secret key (Key⊕RAND) for every authentication process and the new PN Random sequence generator [14]. The suggested generator consists of three Maximal lengths Linear Feedback Shift Register (LFSR) with thirty two, seventeen and fifteen taps. The period of this PN sequence= $(2^{32}-1)$ $(2^{17}-1)$ $(2^{15}-1)$ the 1st 128 bits of the PN sequence generator is taken as the secret key to upgrade the S-box. The 1st 64 bits to rearrange the columns and the 2nd 64 bits to rearrange the rows of original S-box. The feedback functions of the LFSRs are: [15].

LFSR 1: $F_1=X^{15}+X^{14}+1$

LFSR 2: $F_2=X^{32}+X^{22}+X^2+X+1$

LFSR 3: $F_3= X^{17}+X^{14}+1$

To initialize the PN sequence generator as shown fig.4, the new secret key is divided into two vectors of 64 bit length that are XORed to produce the initial state of the PN sequence generator (64bits). Let the fixed stored authentication key K_i = [6C 38 A1 16 AC 28 0C 45 4F 59 33 2E E3 5C 8C 4F] and the RAND = [EE 64 66 BC 96 20 2C 5A 55 7A BB EF F8 BA BF 63], the new secret key = $K_i \oplus$RAND = [82 5C C7 AA 3A 08 20 1F 1A 23 88 C1 1B E6 33 2C]. The initialization vector of the PN sequence generator (reshaped new secret key) = [98 7F 4F 6B 21 EE 13 33]. The 1st 64 bits of the PN sequence generator will be [324E8C5160BAD97F] used to rearrange columns of S-box and the 2nd 64 bits of the PN sequence generator will be [F3A1597682CEBD40] to rearrange the rows of S-box to have the final modified form.

V. DISCUSSION AND CONCLUSIONS

(i) The main weakness in Milenage, as stated by the cryptanalysts, is the use of bit rotations and constant XORs in the middle part of the milenage. Specially, if the kernel block cipher in milenage algorithm is susceptible to differential cryptanalysis, then an attacker is capable to do a variety of attacks on milenage algorithm. An attacker cannot predict any useful information if the kernel block cipher in milenage algorithm is a strong secure.

This paper modifies the standard Milenage Authentication algorithm through the dynamic change of the kernel block cipher AES. For every Authentication process a new S-box will be generated using a combination of received random sequence number (RAND), stored Authentication key (K_i) and PN sequence generator to rearrange the columns and rows of standard S-box in AES. Tests proved that the modified AES is more secure than the standard one, due to its dynamic structure. In addition to increasing its immunity to linear and differential cryptanalysis as shown by avalanche test results in table 10.

TABLE 10. AVERAGE VALUE OF AVALANCHE TESTS FOR (PLAIN TEXT – SECRET KEY) IN AES AND MODIFIED AES.

Input type of data	Type of algorithm	Avalanche average value
Plaintext	Modified AES	50.15%
Plaintext	AES	49.71%
Secret key	Modified AES	49.86%
Secret key	AES	49.84%

(ii) Execution time can be reduced as follows:

MILENAGE algorithm with all the functions f1 to f5* are designed and implemented on an IC card processing with a 8-bit microprocessor running at 3.25 MHz with 8 kbyte ROM and 300byte RAM and produce AK, XMAC-A, RES, CK and IK in less than 500 ms execution time.[19].

Modified MILENAGE algorithm with all the functions f1 to f5* are designed and implemented on a microcontroller (PIC18F452) processing with 8-bit microprocessor running at 11.0592 MHz with 32 Kbyte ROM [6450 program bytes used from a possible 32768 (19.68%)] and 1536 byte RAM [1232 variable bytes used from a possible 1536 (80.21%)] and produce AK, XMAC-A, RES, CK and IK in 50.333 ms execution time.
